Water vapor content and instability indices from SEVIRI + NWP data

Every 3/1 hours

Every 15/5 minutes

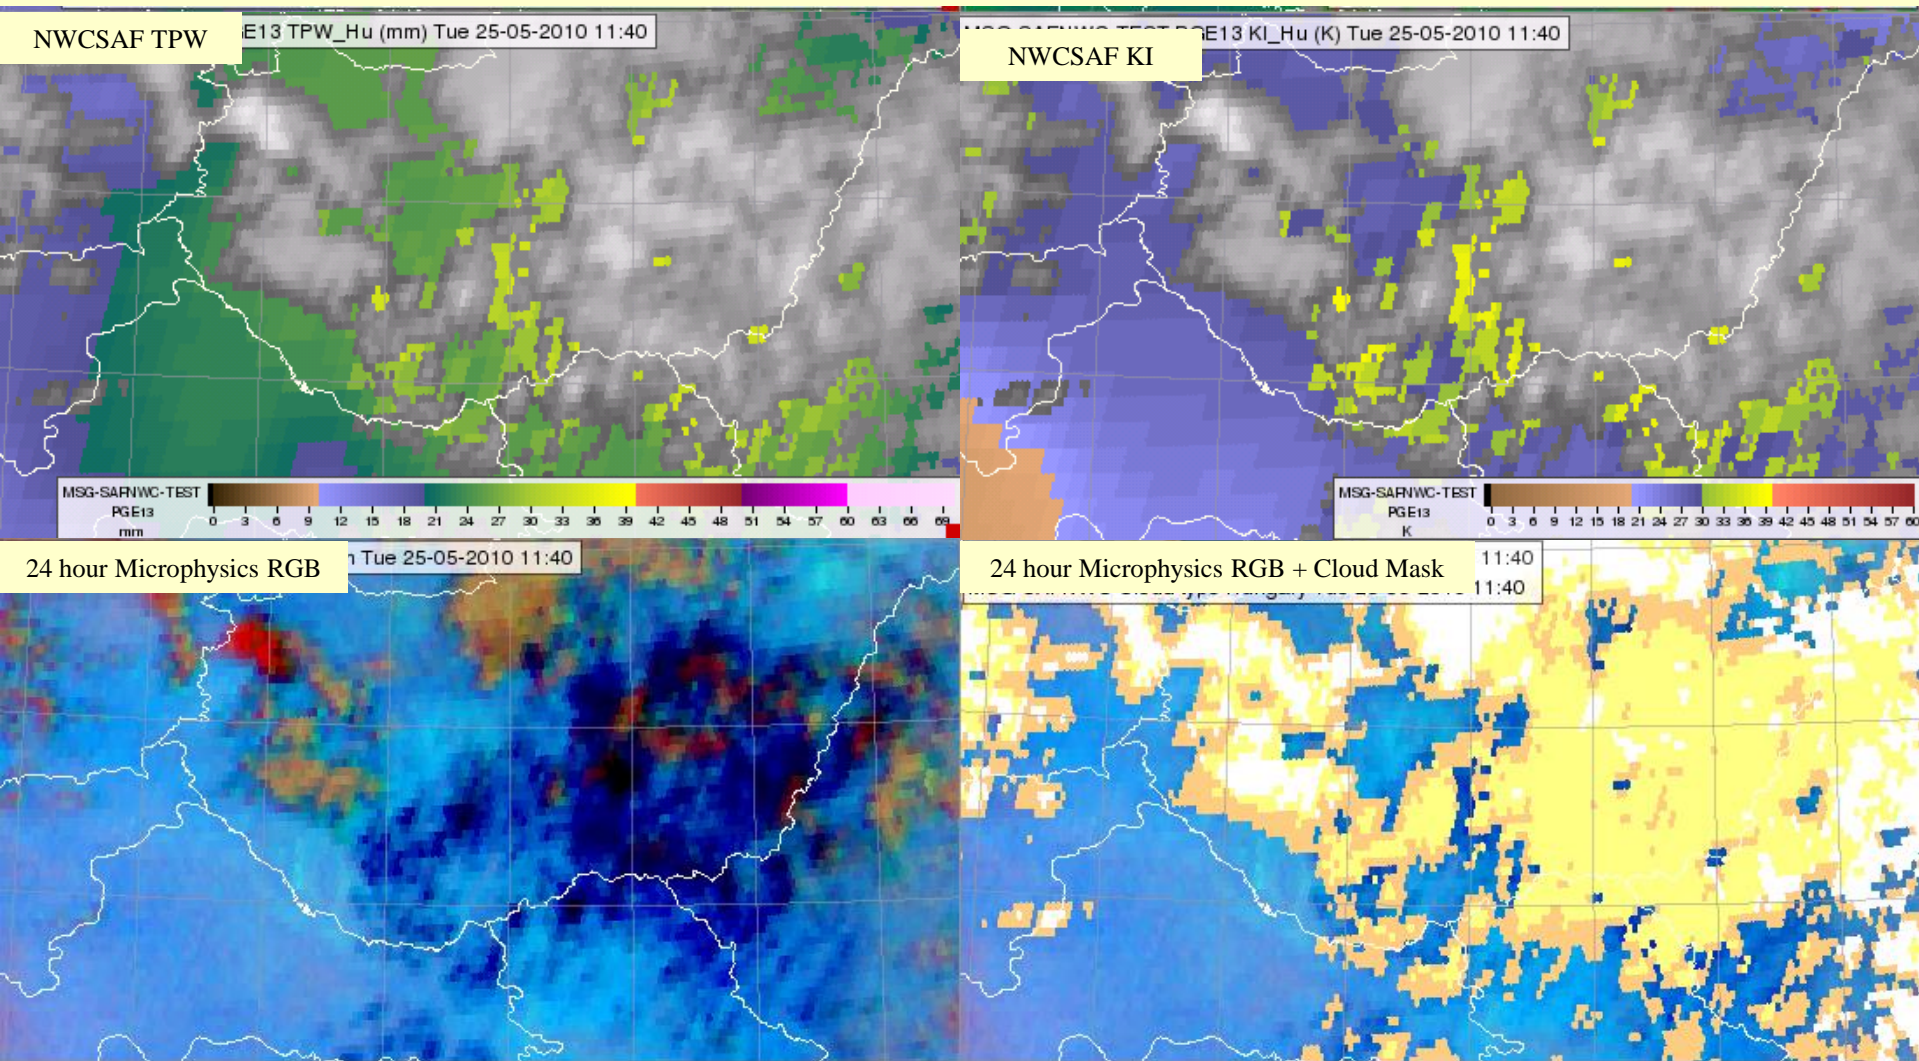

Excellent **temporal resolution: 15/5 minutes** - essential at convection monitoring/forecasting.

The **spatial resolution is good**. The nominal spatial resolution is **9 x 9 km** by default. It can be reduced to 3 x 3 km.

Only for cloud-free areas - no microwave channels

For a pixel misdetected as cloud-free the algorithm retrieves too moist and unstable atmosphere

(for a cloud-free pixel at 12 UTC)

The background data of SPhR is ECMWF, it makes a correction to it.

In this case the correction was made in good direction, ECMWF was improved.

SAFNWC-TEST PGE13 DiffML_Hu (mm) Tue 25-05-2010 11:55

	TEMP	SPhR	ECMWF (00+12)
TPW [mm]	20.24	21.2	23.6
K-index [°C]	26.1	24.7	26.9

Definitions of the instability indices:

Lifted Index:

LI = $T(500) - T(\text{lifted adiabatically from the 'lowest 100 hPa' to 500 hPa})$,

where $T(500)$ is the temperature of the environment at 500 hPa.

The air parcel is lifted adiabatically from 'inside' the 100 hPa thick layer just above the surface to 500 hPa and its temperature is compared to that of the environment. The initial temperature and humidity of the virtual lifted parcel are the average values of this layer.

Showalter Index:

SHW = $T(500) - T(\text{lifted adiabatically from 850hPa to 500 hPa})$,

where $T(500)$ is the temperature of the environment at 500 hPa pressure level.

The air parcel is adiabatically lifted from 850 hPa to 500 hPa and its temperature is compared to that of the environment.

K-Index:

KI = $(T(850) - T(500)) + TD(850) - (T(700) - TD(700))$)

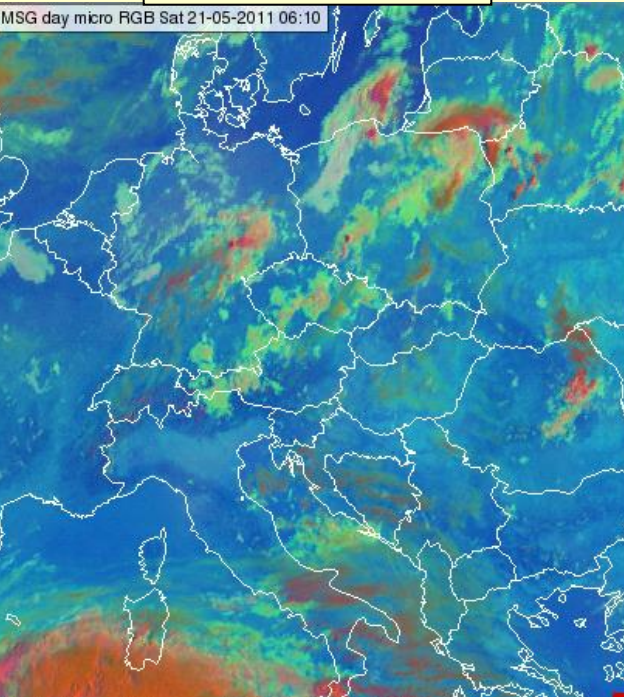

where $T(p)$ is the observed temperature and $TD(p)$ is the dew point temperature at p hPa pressure level.

Would you expect thunderstorm initiation above Poland in the afternoon?

31 May 2011

13:25 UTC

Day Microphysics RGB

$$\text{K-Index} = (T(850) - T(500)) + TD(850) - (T(700) - TD(700))$$

K-Index was low because the 700 hPa dew point depression was high.

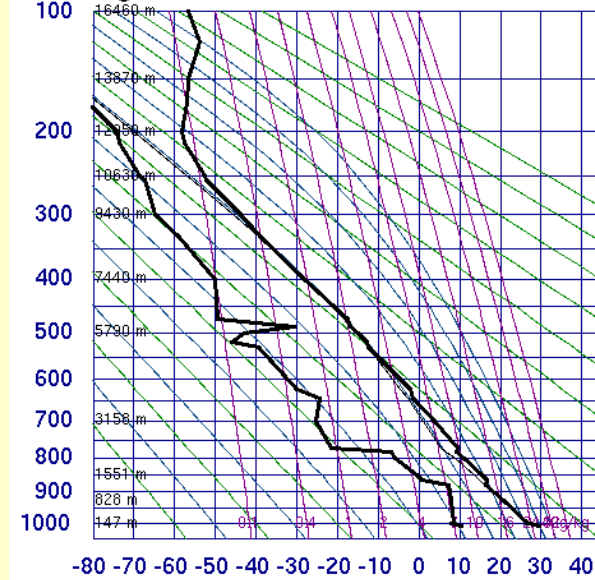

Lifted Index:

$$\text{LI} = T(500) - T(\text{lifted adiabatically from the 'lowest 100 hPa' to 500 hPa}),$$

The definition of Lifted Index does not include any information from around 700 hPa, only about the near surface environment and the 500 hPa environment. The Lifted Index values seem to be not affected by the very dry mid layer. Calculating the Lifted Index it is supposed that the virtual air parcel is lifted **adiabatically** up to 500 hPa. However, in reality the 'lifting' could not be really adiabatic, **some mixing with the environment is very likely to happen.**

Showalter-Index

Good accordance with the satellite retrieving.

The Lifted and Showalter Indices are high positive. The CAPE is negligible.

The K-Index was rather high **also** according the radiosonde measurements (29.7 °C).

Radiosonde measurements in Ankara, Turkey at 12 UTC

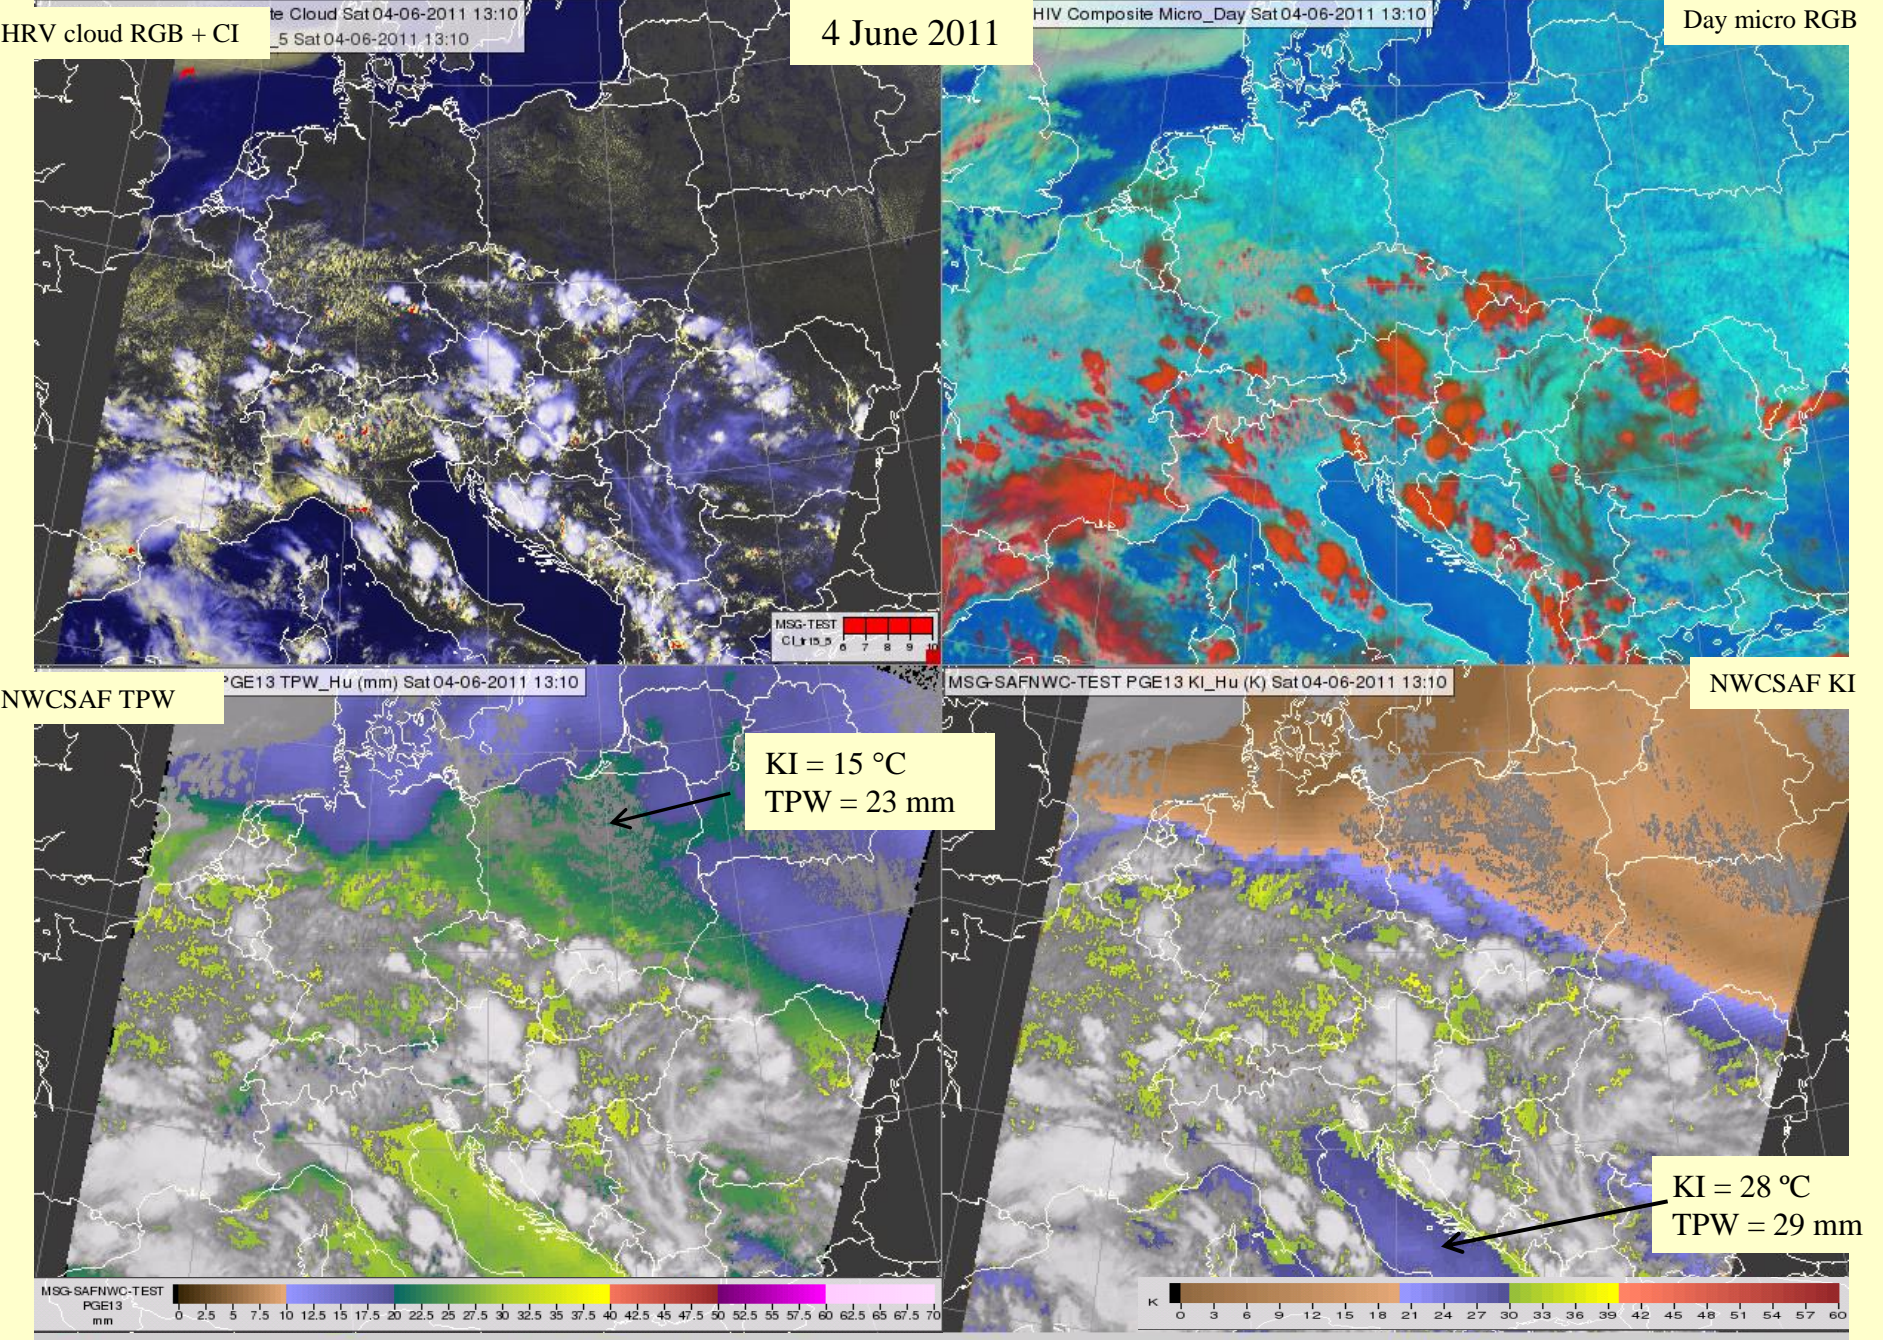

$$\text{K-Index} = (T(850) - T(500)) + TD(850) - (T(700) - TD(700))$$

where $T(p)$ is the observed temperature and $TD(p)$ is the dew point temperature at p hPa pressure level.

The K-Index was high due to the moist layer at around 700 hPa, and the fact that the dew point temperature at 500 hPa is not included in its definition.

These examples show that the different definitions of the indices capture different situations. In such a 'contradicting' case the forecaster should try to understand what the reason of the differences is, and should look the combination of values.

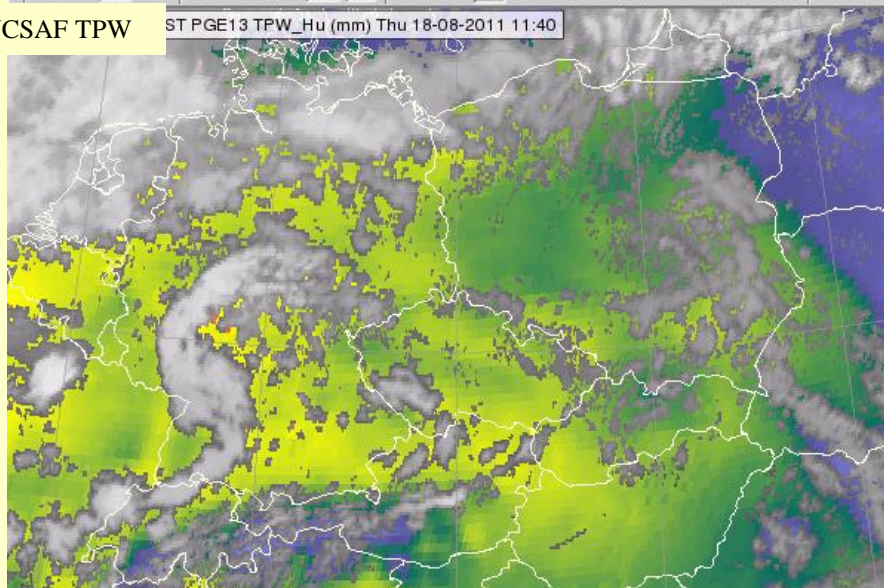

Moist and unstable environment without deep convection – Adriatic Sea – no lift – no convection

South Germany - high TPW (up to 36 mm) and K-index (up to 38 °C), but no convection

Instability indices over mountains

We found (slightly) **positive Lifted Indices over mountainous** terrain in cases when convective clouds develop. How can it happen, as positive Lifted Index is supposed to indicate stable environment?

It can happen that the Lifted Index is really positive. **Weak convection is possible for 1-3 K Lifted Index if strong lifting is present.**

- The thunderstorm might originate from a valley (from below the ‘lowest 100 hPa over the surface’.)
- The mountains may lift the parcel above the ‘lower 100 hPa layer’ where (the stratification of) the atmosphere may be more unstable.

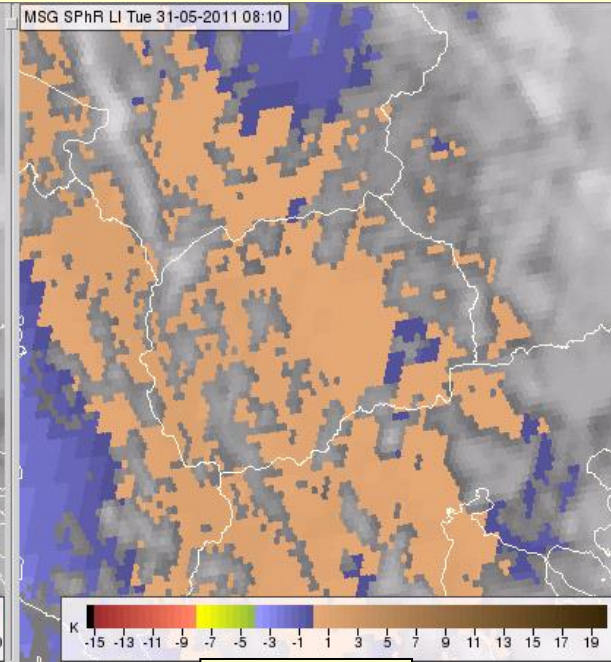

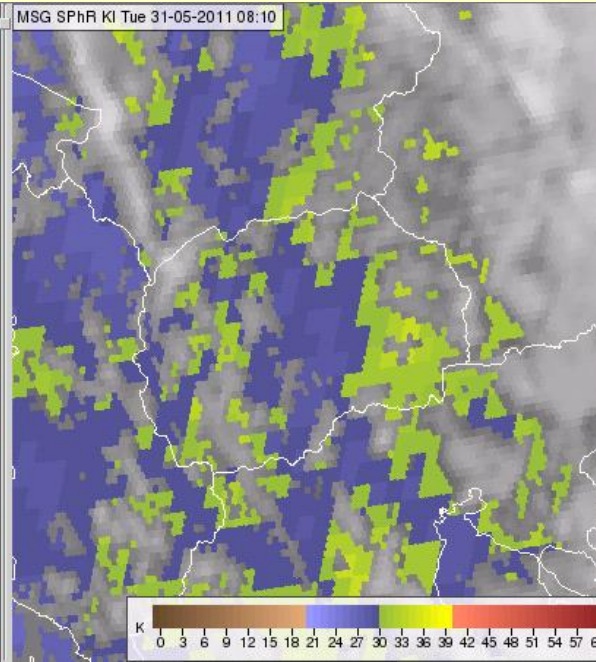

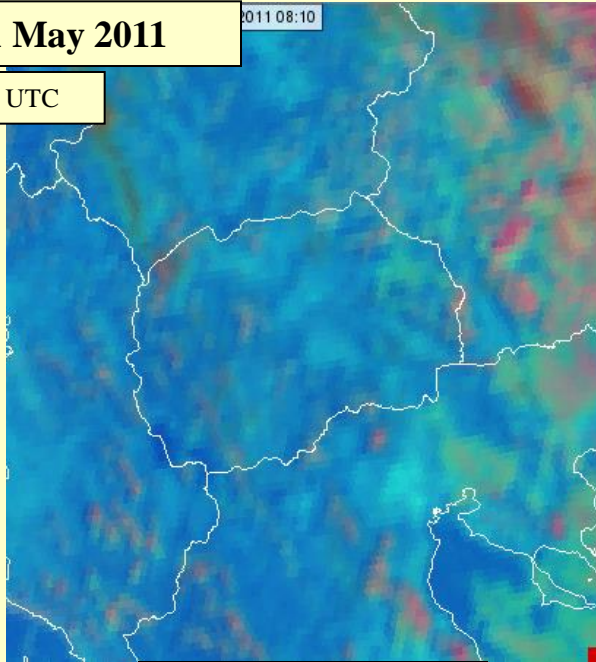

It can happen that the positive value of the Lifted Index is a mistake. **The Lifted Index retrieval is more uncertain over mountainous region.** The errors in the retrieval processing could be large due to **different topographies** (real topography, topography used in NWP model and in the satellite retrieval).

The **Lifted Index is closer to zero** anyway over mountains as the virtual air parcel is lifted from a pressure level closer to 500 hPa.

The lifted index is often close to zero over mountains. Thunderstorms may form also for positive lifted indices (0-2 K).

Conclusions

useful information on the convective environment: (total and 3 layer) water vapor content and instability indices.

Synergy of NWP forecast and satellite observation.

It **highly increase the temporal resolution** and slightly correct the vertical profile of the moisture.

This small correction might be useful. **It might reflect better the local moisture gradient / moisture boundaries.** **Added value to the NWP forecast**

All the **instability indices** intend to characterize the instability of the atmosphere – with **different definitions** with **different approximations** – they should be used together - in case of contradiction the user should try to understand the reason of the differences.

High water vapor content and instability are not enough for deep convection. **Lifting (triggering) mechanism** is also needed.

The **non-detected thin cirrus clouds** may cause too high environmental parameters.

Over mountains we found lifted index around zero – in case storm formed.

A Product Tutorial will be published on the EUMeTrain website in 2014 <http://www.eumetrain.org/>

The SPhR products were created by the SAFNWC/MSGv2012 software

Thank you for the attention!

Supercell Composite Parameter

A multiple ingredient, composite index that includes effective storm-relative helicity (ESRH, based on Bunkers right supercell motion), most unstable parcel CAPE (muCAPE), and effective bulk wind difference (EBWD). Each ingredient is normalized to supercell "threshold" values, and larger values of SCP denote greater "overlap" in the three supercell ingredients. Only positive values of SCP are displayed, which correspond to environments favoring right-moving (cyclonic) supercells.

This index is formulated as follows:

$$\text{SCP} = (\text{muCAPE} / 1000 \text{ J kg}^{-1}) * (\text{ESRH} / 50 \text{ m}^2 \text{ s}^{-2}) * (\text{EBWD} / 20 \text{ m s}^{-1})$$

EBWD is divided by 20 m s⁻¹ in the range of 10-20 m s⁻¹. EBWD less than 10 m s⁻¹ is set to zero, and EBWD greater than 20 m s⁻¹ is set to one.
